Convergence of Value Aggregation for Imitation Learning

Ching-An Cheng

Abstract

Value aggregation is a general framework for solving imitation learning problems. Based on the idea of data aggregation, it generates a policy sequence by iteratively interleaving policy optimization and evaluation in an online learning setting. While the existence of a good policy in the policy sequence can be guaranteed non-asymptotically, little is known about the convergence of the sequence or the performance of the last policy. In this paper, we debunk the common belief that value aggregation always produces a convergent policy sequence with improving performance. Moreover, we identify a critical stability condition for convergence and provide a tight non-asymptotic bound on the performance of the last policy. These new theoretical insights let us stabilize problems with regularization, which removes the inconvenient process of identifying the best policy in the policy sequence in stochastic problems.

1 INTRODUCTION

Reinforcement learning (RL) is a general framework for solving sequential decision problems (Sutton and Barto, 1998). Using policy gradient methods, it has demonstrated impressive results in GO (Silver et al., 2016) and video-game playing (Mnih et al., 2013). However, due its generality, it can be difficult to learn a policy sample-efficiently or to characterize the performance of the found policy, which is critical in applications that involves real-world costs, such as robotics (Pan et al., 2017). To better exploit the domain knowledge about a problem, one popular approach is imitation learning (IL) (Pomerleau, 1989).

This inconvenience incentivizes practitioners to just return the last policy \( \pi_N \) (Laskey et al., 2017), and, anecdotally, the last policy \( \pi_N \) has been reported to have good empirical performance (Ross et al., 2013; Pan et al., 2017). Supporting this heuristic is the insight that the last policy \( \pi_N \) is trained with all observations and therefore ideally should perform the best. Indeed, such idealism works when all the data are sampled i.i.d., as in the traditional batch learning problems (Vapnik, 1998). However, because here new data
are collected using the updated policy in each iteration, whether such belief applies depends on the convergence of the distributions generated by the policy sequence.

While Ross and Bagnell (2014) alluded that “...the distribution of visited states converges over the iterations of learning,” we show this is not always true—the convergence is rather problem-dependent. In this paper, we identify a critical stability constant \( \theta \) that determines the convergence of the policy sequence. We show that there is a simple example (in Section 4) in which the policy sequence diverges when \( \theta > 1 \). In Section 5, we provide tight non-asymptotic bounds on the performance of the last policy \( \pi_N \), in both deterministic and stochastic problems, which implies that the policy sequence always converges when \( \theta < 1 \). Our new insight also suggests that the stability of the last policy \( \pi_N \) can be recovered by regularization, as discussed in Section 6.

2 PROBLEM SETUP

We consider solving a discrete-time RL problem. Let \( \mathcal{S} \) be the state space and \( \mathcal{A} \) be the action space of an agent. Let \( \Pi \) be the class of policies and let \( T \) be the length of the planning horizon.\(^1\) The objective of the agent is to search for a policy \( \pi \in \Pi \) to minimize an accumulated cost \( J(\pi) \):

\[
\min_{\pi \in \Pi} J(\pi) := \min_{\pi \in \Pi} \mathbb{E}_{\rho_\pi} \left[ \sum_{t=0}^{T-1} c_t(s_t, a_t) \right] \tag{1}
\]

in which \( c_t \) is the instantaneous cost at time \( t \), and \( \rho_\pi \) denotes the trajectory distribution of \((s_t, a_t) \in \mathcal{S} \times \mathcal{A}, \text{for} \ t = 1, \ldots, T, \text{under policy} \ a_t \sim \pi(s_t) \) given a prior distribution \( \rho_0(s_0) \). Note that we do not place assumptions on the structure of \( \mathcal{S} \) and \( \mathcal{A} \) and the policy class \( \Pi \). To simplify the notation, we write \( \mathbb{E}_{a \sim \pi} \) even if the policy is deterministic.

For notation: we denote \( Q_{\pi|t}(s, a) \) as the Q-function at time \( t \) under policy \( \pi \) and \( V_{\pi|t}(s) = \mathbb{E}_{a \sim \pi}[Q_{\pi|t}(s, a)] \) as the associated value function. In addition, we introduce some shorthand: we denote \( d_{\pi|t}(s) \) as the state distribution at time \( t \) generated by running the policy \( \pi \) for the first \( t \) steps, and define a joint distribution \( d_{\pi}(s, t) = d_{\pi|t}(s)U(t) \), where \( U(t) \) is the uniform distribution over the set \( \{0, \ldots, T-1\} \). Due to space limitations, we will often omit explicit dependencies on random variables in expectations, e.g. we will write

\[
\min_{\pi \in \Pi} \mathbb{E}_{d_{\pi}} [c_t] \tag{2}
\]

to denote \( \min_{\pi \in \Pi} \mathbb{E}_{s, t \sim d_{\pi}} \mathbb{E}_{a \sim \pi}[c_t(s, a)] \), which is equivalent to \( \min_{\pi \in \Pi} \bar{T} J(\pi) \) (by definition of \( d_{\pi} \)).

3 VALUE AGGREGATION

Solving general RL problems is challenging. In this paper, we focus on a particular scenario, in which the agent, or the learner, has access to an expert policy \( \pi^* \) from which the learner can query demonstrations. Here we embrace a general notion of expert. While it is often preferred that the expert is nearly optimal in (1), the expert here can be any policy, e.g. the agent’s initial policy. Note, additionally, that the RL problem considered here is not necessarily directly related to a real-world application; it can be a surrogate problem which arises in solving the true problem.

The goal of IL is to find a policy \( \pi \) that outperforms or behaves similarly to the expert \( \pi^* \) in the sense that \( J(\pi) \leq J(\pi^*) + O(T) \). That is, we treat IL as performing a robust, approximate policy iteration step from \( \pi^* \): ideally IL should lead to a policy that outperforms the expert, but it at least returns a policy that performs similarly to the expert.

AGGREVAte (Aggregate Value to Imitate) is an IL algorithm proposed by Ross and Bagnell (2014) based on the idea of online convex optimization (Hazan et al., 2016). Here we give a compact derivation and discuss its important features in preparation for the analysis in Section 5. To this end, we introduce the performance difference lemma due to Kakade and Langford (2002), which will be used as the foundation to derive AGGREVAte.

Lemma 1. (Kakade and Langford, 2002) Let \( \pi \) and \( \pi' \) be two policies and \( A_{\pi'|t}(s, a) = Q_{\pi'|t}(s, a) - V_{\pi'|t}(s) \) be the (dis)advantage function at time \( t \) with respect to running \( \pi' \). Then it holds that

\[
J(\pi) = J(\pi') + T \mathbb{E}_{s, t \sim d_{\pi}} \mathbb{E}_{a \sim \pi}[A_{\pi'|t}(s, a)]. \tag{3}
\]

3.1 Motivation

The main idea of AGGREVAte is to minimize the performance difference between the learner’s policy and the expert policy, which, by Lemma 1, is given as

\[
\frac{1}{T} (J(\pi) - J(\pi^*)) = \mathbb{E}_{d_{\pi}} \mathbb{E}_{\pi}[A_{\pi'|t}(s, a)]. \tag{4}
\]

AGGREVAte can be viewed as solving an RL problem with \( A_{\pi'|t}(s, a) \) as the instantaneous cost at time \( t \):

\[
\min_{\pi \in \Pi} \mathbb{E}_{d_{\pi}} \mathbb{E}_{\pi}[A_{\pi'|t}]. \tag{4}
\]

Although the transformation from (2) to (4) seems trivial, it unveils some critical properties. Most importantly, the range of the problem in (4) is normalized. For example, regardless of the original definition of \( c_t \),
if $\Pi \ni \pi^*$, there exists at least a policy $\pi \in \Pi$ such that (4) is non-positive (i.e. $J(\pi) \leq J(\pi^*)$). As now the problem (4) is relative, it becomes possible to place a qualitative assumption to bound the performance in (4) in terms of some measure of expressiveness of the policy class $\Pi$.

We formalize this idea into Assumption 1, which is one of the core assumptions implicitly imposed by Ross and Bagnell (2014). To simplify the notation, we define a function $F$ such that for any two policies $\pi, \pi'$

$$
F(\pi', \pi) := \mathbb{E}_{d_{\pi'}} \mathbb{E}_\pi [A_{\pi'|\pi}].
$$

This function captures the main structure in (4). By separating the roles of $\pi'$ (which controls the state distribution) and $\pi$ (which controls the action/prediction), the performance of a policy class $\Pi$ relative to an expert $\pi^*$ can be characterized with the approximation error in a supervised learning problem.

**Assumption 1.** Given a policy $\pi^*$, the policy class $\Pi$ satisfies that for arbitrary sequence of policies $\{\pi_n \in \Pi\}_{n=1}^N$, there exists a small constant $\epsilon_{\Pi, \pi^*}$ such that

$$
\min_{\pi \in \Pi} \frac{1}{N} \sum_{n=1}^N f_{1:n}(\pi) \leq \epsilon_{\Pi, \pi^*},
$$

where $f_n(\pi) := F(\pi_n, \pi)$ and $f_{1:n}(\pi) = \sum_{n=1}^N f_n(\pi)$.

This assumption says that there exists at least a policy $\pi \in \Pi$ which is as good as $\pi^*$ in the sense that $\pi$ can predict $\pi^*$ well in a cost-sensitive supervised learning problem, with small error $\epsilon_{\Pi, \pi^*}$, under the average state distribution generated by an arbitrary policy sequence $\{\pi_n \in \Pi\}_{n=1}^N$.

Following this assumption, AGGREGATE exploits another critical structural property of the problem.

**Assumption 2.** $\forall \pi' \in \Pi, F(\pi', \pi)$ is a strongly convex function in $\pi$.

While Ross and Bagnell (2014) did not explicitly discuss under which condition Assumption 2 holds, here we point out some examples (proved in Appendix A).

**Proposition 1.** Suppose $\Pi$ consists of deterministic linear policies (i.e. $a = \phi(s)^T x$ for some feature map $\phi(s)$ and weight $x$) and $\forall s \in \mathbb{S}, c_1(s, \cdot)$ is strongly convex. Assumption 2 holds under any of the following:

1. $V_{\pi^*|\cdot}(s)$ is constant over $\mathbb{S}$ (in this case $A_{\pi^*|\cdot}(s, a)$ is equivalent to $c_1(s, a) + a \text{ constant}$)

2. The problem is continuous-time and the dynamics are affine in action.

We further note that AGGREGATE has demonstrated impressive empirical success even when Assumption 2 cannot be verified (Sun et al., 2017; Pan et al., 2017).

### 3.2 Algorithm and Performance

Given Assumption 2, AGGREGATE treats $f_n(\cdot)$ as the per-round cost in an online convex optimization problem and updates the policy sequence as follows: Let $\pi_1$ be an initial policy. In the $n$th iteration of AggreVaTe, the policy is updated by

$$
\pi_{n+1} = \arg \min_{\pi \in \Pi} f_{1:n}(\pi).
$$

After $N$ iterations, the best policy in the sequence $\{\pi_n\}_{n=1}^N$ is returned, i.e. $\pi = \pi_N$, where

$$
\hat{\pi}_N := \arg \min_{\pi \in \{\pi_n\}_{n=1}^N} J(\pi).
$$

As the update rule (7) (aka Follow-the-Leader) has a sublinear regret, it can be shown that (cf. Section 5.1)

$$
J(\hat{\pi}_N) \leq J(\pi^*) + T(\epsilon_{\text{class}} + \epsilon_{\text{regret}}),
$$

in which $\epsilon_{\text{regret}} = O(1/N)$ is the average regret and

$$
\epsilon_{\text{class}} := \min_{\pi \in \Pi} \frac{1}{N} \sum_{n=1}^N \mathbb{E}_{d_{\pi_n}} \left[ \mathbb{E}_{\pi} [Q_{\pi^*}|\cdot] - \mathbb{E}_{\pi^*} [Q_{\pi^*}|\cdot] \right]
$$

compares the best policy in the policy class $\Pi$ and the expert policy $\pi^*$. The term $\epsilon_{\text{class}}$ can be negative if there exists a policy in $\Pi$ that is better than $\pi^*$ under the average state distribution, $\frac{1}{N} \sum_{n=1}^N d_{\pi_n}$, generated by AGGREGATE. By Assumption 1, $\epsilon_{\text{class}} \leq \epsilon_{\Pi, \pi^*}$, we know $\epsilon_{\text{class}}$ at least should be small.

The performance bound in (9) satisfies the requirement of IL that $J(\hat{\pi}_N) \leq J(\pi^*) + O(T)$. Especially because $\epsilon_{\text{class}}$ can be non-positive, AGGREGATE can be viewed as robustly performing one approximate policy iteration step from $\pi^*$.

One notable special case of AGGREGATE is DAGGER (Ross et al., 2011). DAGGER tackles the problem of solving an unknown RL problem by imitating a desired policy $\pi^*$. The reduction to AGGREGATE can be seen by setting $c_1(s, a) = \mathbb{E}_{\pi^*} [Q_{\pi^*}|\cdot][a - a^*]$, i.e. $c_1(s, a)$ is strongly convex and $\forall s \in \mathbb{S}, c_1(s, \cdot)$ is strongly convex. Assumption 2 holds under any of the following:

1. $V_{\pi^*|\cdot}(s)$ is constant over $\mathbb{S}$ (in this case $A_{\pi^*|\cdot}(s, a)$ is equivalent to $c_1(s, a) + a \text{ constant}$)

2. The problem is continuous-time and the dynamics are affine in action.
4 GUARANTEE ON THE LAST POLICY?

The performance bound in Section 3 implicitly assumes that the problem is either deterministic or that infinite samples are available in each iteration. For stochastic problems, \( f_{1:n} \) can be approximated by finite samples or by function approximators (Ross and Bagnell, 2014). Suppose \( m \) samples are collected in each iteration to approximate \( f_n \). An additional error in \( O(\frac{1}{\sqrt{mN}}) \) will be added to the performance of \( \hat{\pi}_N \). However, in practice, another constant statistical error\(^4\) in \( O(\frac{1}{m}) \) is introduced when one attempts to identify \( \hat{\pi}_N \) from the sequence \( \{\pi_n\}_{n=1}^N \).

This practical issue motivates us to ask whether a similar guarantee applies to the last policy \( \pi_N \) so that the selection process to find \( \hat{\pi}_N \) can be removed. In fact, the last policy \( \pi_n \) has been reported to have good performance empirically (Ross et al., 2013; Pan et al., 2017). It becomes interesting to know what one can say about \( \pi_N \). It turns out that running AGGREGVATE does not always yield a policy sequence \( \{\pi_n\} \) with reasonable performance, as given in the example below.

**A Motivating Example** Consider a two-stage deterministic optimal control problem:

\[
\min_{\pi \in \Pi} J(\pi) = \min_{\pi \in \Pi} c_1(s_1, a_1) + c_2(s_2, a_2)
\]

where the transition and costs are given as

\[
s_1 = 0, \quad s_2 = \theta(s_1 + a_1), \quad c_1(s_1, a_1) = 0, \quad c_2(s_2, a_2) = (s_2 - a_2)^2.
\]

Since the problem is deterministic, we consider a policy class \( \Pi \) consisting of open-loop stationary deterministic policies, i.e. \( a_1 = a_2 = x \) for some \( x \) (for convenience \( \pi \) and \( x \) will be used interchangeably). It can be easily seen that \( \Pi \) contains a globally optimal policy, namely \( x = 0 \). We perform AGGREGVATE with a feedback expert policy \( a_1^\ast = s_1 \) and some initial policy \( |x_1| > 0 \). While it is a custom to initialize \( x_1 = \arg\min_{x \in \mathcal{X}} F(x^\ast, x) \) (which in this case would ideally return \( x_1 = 0 \)), setting \( |x_1| > 0 \) simulates the effect of finite numerical precision.

We consider two cases (\( \theta > 1 \) or \( \theta < 1 \)) to understand the behavior of AGGREGVATE. First, suppose \( \theta > 1 \). Without loss generality, take \( \theta = 10 \) and \( x_1 = 1 \). We can see running AGGREGVATE will generate a divergent sequence \( x_2 = 10, x_3 = 55, x_4 = 220 \ldots \) (in this case AGGREGVATE would return \( x_1 \) as the best policy). Since \( J(x) = (\theta - 1)^2 x^2 \), the performance \( \{J(x_n)\} \) is an increasing sequence. Therefore, we see even in this simple case, which can be trivially solved by gradient descent in \( O(\frac{1}{n}) \), using AGGREGVATE results in a sequence of policies with degrading performance, though the policy class \( \Pi \) includes a globally optimal policy.

Now suppose on the contrary \( \theta < 1 \). We can see that \( \{x_n\} \) asymptotically converges to \( x^\ast = 0 \).

This example illustrates several important properties of AGGREGVATE. It illustrates that whether AGGREGVATE can generate a reasonable policy sequence or not depends on intrinsic properties of the problem (i.e. the value of \( \theta \)). The non-monotonic property was also empirically found in Laskey et al. (2017). In addition, it shows that \( \epsilon_{\Pi, x^\ast} \) can be large while \( \Pi \) contains an optimal policy.\(^5\) This suggests that Assumption 1 may be too strong, especially in the case where \( \Pi \) does not contain \( x^\ast \).

5 THEORETICAL ANALYSIS

Motivated by the example in Section 4, we investigate the convergence of the policy sequence generated by AGGREGVATE in general problems. We assume the policy class \( \Pi \) consists of policies parametrized by some parameter \( x \in \mathcal{X} \), in which \( \mathcal{X} \) is a convex set in a normed space with norm \( \| \cdot \| \) (and \( \| \cdot \|_\ast \), as its dual norm). With abuse of notation, we abstract the RL problem in (4) as

\[
\min_{x \in \mathcal{X}} F(x, x)
\]

where we overload the notation \( F(\pi^\prime, \pi) \) defined in (5) as \( F(\pi^\prime, \pi) = F(y, x) \) when \( \pi, \pi^\prime \in \Pi \) are parametrized by \( x, y \in \mathcal{X} \), respectively. Similarly, we will write \( f_n(x) = F(x_n, x) \) for short. In this new notation, AGGREGVATE’s update rule in (7) can be simply written as \( x_{n+1} = \arg\min_{x \in \mathcal{X}} f_{1:n}(x) \).

Here we will focus on the bound on \( F(x, x) \), because, for \( x \) parameterized by \( x \), this result can be directly translated to a bound on \( J(\pi) \) by definition of \( F \) in (5) and Lemma 1, \( J(\pi) = J(\pi^\ast) + TF(\pi, \pi) \). For simplicity, we will assume for now \( F \) is deterministic; the convergence in stochastic problems will be discussed at the end of the section.

\(^4\)The original analysis in the stochastic case by Ross and Bagnell (2014) only guarantees the existence of a good policy in the sequence. The \( O(\frac{1}{\sqrt{mN}}) \) error is due to identifying the best policy (Lee et al., 1998) (as the function is strongly convex) and the \( O(\frac{1}{mn}) \) error is the generalization error (Cesa-Bianchi et al., 2004).

\(^5\)In this example, \( \epsilon_{\Pi, x^\ast} \) can be arbitrarily large unless \( \mathcal{X} \) is bounded. However, even when \( \epsilon_{\Pi, x^\ast} \) is bounded, the performance of the policy sequence can be non-monotonic.
5.1 Classical Result

For completeness, we restate the structural assumptions made by AGGREVATE in terms of $\mathcal{X}$ and review the known convergence of AGGREVATE (Ross and Bagnell, 2014).

**Assumption 3.** Let $\nabla_2$ denote the derivative with respect to the second argument.

1. $F$ is uniformly $\alpha$-strongly convex in the second argument: $\forall x, y, z \in \mathcal{X}$, $F(z, x) \geq F(z, y) + \langle \nabla_2 F(z, y), x - y \rangle + \frac{\alpha}{2} \|x - y\|^2$.

2. $F$ is uniformly $G_2$-Lipschitz continuous in the second argument: $\forall x, y, z \in \mathcal{X}$, $|F(z, x) - F(z, y)| \leq G_2 \|x - y\|$.

**Assumption 4.** $\forall \{x_n \in \mathcal{X}\}_{n=1}^\infty$, there exists a small constant $\epsilon_{\Pi, \pi^*}$ such that $\min_{x \in \mathcal{X}} \frac{1}{N} f_1: N(x) \leq \epsilon_{\Pi, \pi^*}$.

**Theorem 1.** Under Assumption 3 and 4, AGGREVATE generates a sequence such that, for all $N \geq 1$,

$$F(\hat{x}_N, \check{x}_N) \leq \frac{1}{N} \sum_{n=1}^N f_n(x_n) \leq \epsilon_{\Pi, \pi^*} + \frac{G_2^2 \ln(N) + 1}{2\alpha}$$

where $\hat{x}_N := \arg\min_{x \in \{x_n\}_{n=1}^\infty} F(x_n, x_n)$.

**Proof.** Here we present a sketch (see Appendix A for details). The first inequality is straightforward. To bound the average performance, it can be shown that $\sum_{n=1}^N f_n(x_n) \leq \min_{x \in \mathcal{X}} \frac{1}{N} f_1: N(x) + \sum_{n=1}^N f_1: N(x_n) - f_1: N(x_{n+1})$. Since $x_n$ minimizes $f_1: N - 1$ and $f_1: N$ is $\alpha$-strongly convex, $f_1: N(x_n)$ is upper bounded by $\frac{\|\nabla f_1: N(x_n)\|_*}{2\alpha} \leq G_2$. This concludes the proof.

5.2 New Structural Assumptions

AGGREVATE can be viewed as an attempt to solve the optimization problem in (11) without any information (not even continuity) regarding how $F(x, x)$ changes with perturbations in the first argument. Since making even a local improvement for general Lipschitz continuous problems is known to be NP-hard (Nesterov, 2013), the classical performance guarantee of AGGREVATE is made possible, only because of the additional structure given in Assumption 4. However, as discussed in Section 4, Assumption 4 can be too strong and is yet insufficient to determine if the performance of the last policy can improve over iterations. Therefore, to analyze the performance of the last policy, we require additional structure on $F$.

Here we introduce a continuity assumption.

**Assumption 5.** $\nabla_2 F$ is uniformly $\beta$-Lipschitz continuous in the first argument: $\forall x, y, z \in \mathcal{X}$ \noindent $\|\nabla_2 F(x, z) - \nabla_2 F(y, z)\|_* \leq \beta \|x - y\|$.

Because the first argument of $F$ in (5) defines the change of state distribution, Assumption 5 basically requires that the expectation over $d_\pi$ changes continuously with respect to $\pi$, which is satisfied in most RL problems. Intuitively, this quantifies the difficulty of a problem in terms of how sensitive the state distribution is to policy changes.

In addition, we relax Assumption 4. As shown in Section 4, Assumption 4 is sometimes too strong, because it might not be satisfied even when $\Pi$ contains a globally optimal policy. In the analysis of convergence, we instead rely on a necessary condition of Assumption 4, which is satisfied by the example in Section 4.

**Assumption 6.** Let $\pi$ be a policy parametrized by $x$. There exists a small constant $\epsilon_{x, \pi^*}$ such that $\forall x \in \mathcal{X}$, $\min_{x \in \mathcal{X}} F(x, y) \leq \epsilon_{x, \pi^*}$.

Compared with the global Assumption 4, the relaxed condition here is only local: it only requires the existence of a good policy with respect to the state distribution visited by running a single policy. It can be easily shown that $\epsilon_{x, \pi^*} \leq \epsilon_{\Pi, \pi^*}$.

5.3 Guarantee on the Last Policy

In our analysis, we define a stability constant $\theta = \frac{\beta}{\alpha}$. One can verify that this definition agrees with the $\theta$ used in the example in Section 4. This stability constant will play a crucial role in determining the convergence of $\{x_n\}$, similar to the spectral norm of the Jacobian matrix in discrete-time dynamical systems (Antsaklis and Michel, 2007). We have already shown above that if $\theta > 1$ there is a problem such that AGGREVATE generates a divergent sequence $\{x_n\}$ with degrading performance over iterations. We now show that if $\theta < 1$, then $\lim_{n \to \infty} F(x_n, x_n) \leq \epsilon_{\Pi, \pi^*}$ and moreover $\{x_n\}$ is convergent.

**Theorem 2.** Suppose Assumptions 3, 5, and 6 are satisfied. Let $\theta = \frac{\beta}{\alpha}$. Then for all $N \geq 1$ it holds

$$F(x_N, x_{N+1}) \leq \epsilon_{\Pi, \pi^*} + \frac{(\theta e^{1-\theta} G_2)^2}{2\alpha} N^{2(\theta-1)}$$

and $\|x_N - \bar{x}_N\| \leq \frac{G_2 e^{1-\theta}}{\alpha} N^{\theta-1}$, where $\bar{x}_N = \frac{1}{N} x_{1:N}$. In particular, if $\theta < 1$, then $\{x_n\}_{n=1}^\infty$ is convergent.

Theorem 2 implies that the stability and convergence of AGGREVATE depends solely on the problem properties. If the state distribution $d_\pi$ is sensitive to minor policy changes, running AGGREVATE would fail to provide any guarantee on the last policy. Moreover, Theorem 2 also characterizes the performance of the average policy $\bar{x}_N$ when $\theta < 1$.

The upper bound in Theorem 2 is tight, as indicated in the next theorem. Note a lower bound on
Using the refined bound provided by Lemma 2, we can bound the progress of $S_n$.

**Proposition 2.** Under the assumptions in Lemma 2, for $n \geq 2$, $S_n \leq e^{1-\theta n}S_2$ and $S_2 = \|x_2 - x_1\| \leq G_2/\alpha$.

**Proof.** The bound on $S_2 = \|x_2 - x_1\|$ is due to that $x_2 = \arg\min_{x \in X} f_1(x)$ and that $f_1$ is $\alpha$-strongly convex and $G_2$-Lipschitz continuous.

To bound $S_n$, first we bound $S_{n+1}$ in terms of $S_n$ by

$$S_{n+1} \leq \left(1 - \frac{1}{n}\right) S_n + \|x_{n+1} - x_n\|$$

$$\leq \left(1 - \frac{1}{n} + \frac{\theta}{n}\right) S_n = \left(1 - \frac{1 - \theta}{n}\right) S_n$$

in which the first in equality is due to triangular inequality (i.e. $\|x_k - x_{n+1}\| \leq \|x_k - x_n\| + \|x_n - x_{n+1}\|$) and the second inequality is due to Lemma 2. Let $P_n = \ln S_n$. Then we can bound $P_n - P_{n-1} \leq \sum_{k=2}^{n-1} \ln \left(1 - \frac{1 - \theta}{k}\right) \leq \sum_{k=2}^{n-1} 1 - \frac{1 - \theta}{k} \leq (n - 1)$, where we use the facts that $\ln(1 + x) \leq x$, $\sum_{k=1}^{n-1} \frac{1}{k} \geq \ln(n + 1)$. This implies $S_n = \exp(P_n) \leq e^{1-\theta n}S_2$. 

More generally, define $S_{m:n} = \sum_{n=m}^{m-1} \|x_n - x_k\|$ (i.e. $S_n = S_{1:n}$). Using Proposition 2, we give a bound on $S_{m:n}$. We see that the convergence of $S_{m:n}$ depends mostly on $n$ not $m$. (The proof is given in Appendix.)

**Corollary 1.** Under the assumptions in Lemma 2, for $n > m$, $S_n S_{m:n} \leq O\left(\frac{\theta}{(m-n)\alpha^{\theta - 1}} + \frac{1}{\alpha^{\theta - 1}}\right)$.

Now we are ready prove Theorem 2 by using the concentration of $S_n$ in Proposition 2.

**Proof of Theorem 2.** First, we prove the bound on $F(x_N, x_N)$. Let $x_n := \arg\min_{x \in X} f_n(x)$ and let $f_n = \frac{1}{n} f_1$. Then by $\alpha$-strongly convexity of $f_n$,

$$f_n(x_n) - \min_{x \in X} f_n(x)$$

$$\leq \|\nabla f_n(x_n) - \nabla f_n(x)\|_2$$

$$\leq \|\nabla f_n(x_n) - \nabla f_n(x)\|_2 \leq \frac{1}{2\alpha} \|x_n - x_{n+1}\|^2$$

where the second inequality uses the fact that $x_n = \arg\min_{x \in X} f_{1:n-1}(x)$, the second to the last inequality takes the maximum over $\|x_n - x_{n+1}\|$, and the last inequality uses Assumption 5. Therefore, to bound $f_n(x_n)$, we can use Proposition 2 and Assumption 6:

$$f_n(x_n) = \min_{x \in X} f_n(x) + \frac{\beta^2}{2\alpha} S_n$$

$$\leq e^{1-\theta n}G_2/\alpha$$

Rearranging the terms gives the bound in Theorem 2, and that $\|x_n - \bar{x}_n\| \leq S_n$ gives the second result. Now we show the convergence of $\{x_n\}$ under the condition $\theta < 1$. It is sufficient to show that
\[ \lim_{n \to \infty} \sum_{k=1}^{n} \|x_k - x_{k+1}\| < \infty. \]  
To see this, we apply Lemma 2 and Proposition 2: for \( \theta < 1 \),

\[ \sum_{k=1}^{n} \|x_k - x_{k+1}\| \leq \|x_1 - x_2\| + \sum_{k=2}^{n} \theta S_k \leq c_1 + c_2 \sum_{k=2}^{n} \theta^{2} S_{k-2} < \infty, \]

where \( c_1, c_2 \in O(1) \).

\[ \text{Theorem 4. In addition to Assumptions 5 and 6, assume } f(x; s) \text{ is } \alpha\text{-strongly convex in } x \text{ and } \|f(x; s)\|, < G_2 \text{ almost surely. Let } \theta = \frac{\alpha}{m_0} \text{ and suppose } m_n = m_0 \cdot r^* \text{ for some } r \geq 0. \]  
For all \( N > 0 \), with probability at least 1 - \( \delta \),

\[ F(x_N, x_N) \leq \epsilon_{\Pi, \pi^*} + \tilde{O}\left( \frac{\theta^2 \ln(1/\delta) + C_X}{c \min(\tau, 2, 2 - 2\theta)} \right) \]

\[ + \tilde{O}\left( \frac{\ln(1/\delta) + C_X}{c \min(2, 1 + r)} \right) \]

where \( c = \frac{\alpha}{m_0} \) and \( C_X \) is a constant\(^6\) of the complexity of \( \Pi \).

\[ \text{Proof. The proof is similar to the proof of Theorem 2. To handle the stochasticity, we use a generalization of Azuma-Hoeffding inequality to vector-valued martingales (Hayes, 2005) to derive a high-probability bound on } \|\sum_{t=1}^{n} g_t(x_t) - \nabla f_n(x_n)\|, \text{ and a uniform bound on } \sup_{x \in X} \frac{1}{n} \|\nabla g_t(x) - \nabla f_t(x)\|. \]  
These error bounds allow us to derive a stochastic version of Lemma 2, Proposition 2, and then the performance inequality in the proof of Theorem 2. See Appendix B for the complete proof.

The growth of sample size \( m_n \) over iterations determines the main behavior of AGGREVA in stochastic problems. For \( r = 0 \), compared with Theorem 2, Theorem 4 has an additional constant error in \( \tilde{O}\left( \frac{1}{m_0} \right) \), which is comparable to the stochastic error in selecting the best policy in the classical approach. However, the error here is due to approximating the gradient \( \nabla f_n \) rather than the objective function \( f_n \). For \( r > 0 \), by slightly taking more samples over iterations (e.g.

\[ r = 2 - 2\theta \), we see the convergence rate can get closer to \( \tilde{O}(N^{2-2\theta}) \) as in the ideal case given by Theorem 2. However, it cannot be better than \( \tilde{O}\left( \frac{1}{\sqrt{n}} \right) \). Therefore, for stochastic problems, a stability constant \( \theta < 1/2 \) and a growing rate \( r > 1 \) does not contribute to faster convergence as opposed to the deterministic case in Theorem 2.

Note while our analysis here is based on finite-sample approximation \( g_n(\cdot) = \sum_{k=1}^{m_n} f(\cdot; s_{n,k}) \), the same technique can also be applied to the scenario in the bandit setting and another online regression problem is solved to learn \( f_n(\cdot) \) as in the case considered by Ross and Bagnell (2014). A discussion is given in Appendix C.

The analysis given as Theorem 4 can be viewed as a generalization of the analysis of Empirical Risk Minimization (ERM) to non-i.i.d. scenarios, where the distribution depends on the decision variable. For optimizing a strongly convex objective function with i.i.d. samples, it has been shown by Shalev-Shwartz et al. (2009) that \( x_N \) exhibits a fast convergence to the optimal performance in \( O\left( \frac{1}{\sqrt{n}} \right) \). By specializing our general result in Theorem 4 with \( \theta, r = 0 \) to recover the classical i.i.d. setting, we arrive at a bound on the performance of \( x_N \) in \( O\left( \frac{1}{\sqrt{n}} \right) \), which matches the best known result up to a log factor. However, Theorem 4 is proved by a completely different technique using the martingale concentration of the gradient sequence. In addition, by Theorem 2, the theoretical results of \( x_N \) here can directly translate to that of the mean policy \( \bar{x}_N \), which matches the bound for the average decision \( \bar{x}_N \) given by Kakade and Tewari (2009).

\section{Regularization}

We have shown that whether AGGREVA generates a convergent policy sequence and a last policy with the desired performance depends on the stability constant \( \theta \). Here we show that by adding regularization to the problem we can make the problem stable. For simplicity, here we consider deterministic problems or stochastic problems with infinite samples.

\subsection{Mixing Policies}

We first consider the idea of using mixing policies to collect samples, which was originally proposed as a heuristic by Ross et al. (2011). It works as follows: in the \( n \)th iteration of AGGREVA, instead of using \( F(\pi_n, \cdot) \) as the per-round cost, it uses \( \hat{F}(\pi_n, \cdot) \) which is defined by

\[ \hat{F}(\pi_n, \pi) = \mathbb{E}_{d_{s,n}} \mathbb{E}_{\pi}[A_{\pi^*|s}] \]

The state distribution \( d_{s,n}(s) \) is generated by running \( \pi^* \) with probability \( q \) and \( \pi_n \) with probability \( 1 - q \) at

\[ \text{The constant } C_X \text{ can be thought as } \ln |X|, \text{ where } |X| \text{ measures the size of } X \text{ in e.g. Rademacher complexity or covering number (Mohri et al., 2012). For example, } \ln |X| \text{ can be linear in } \dim X. \]

\[ \]
each time step. Originally, Ross et al. (2011) proposes to set $q$ to decay exponentially over the iterations of AGGREVATE. (The proofs are given in Appendix A.)

Here we show that the usage of mixing policies also has the effect of stabilizing the problem.

Lemma 3. Let $\|p_1 - p_2\|_1$ denote the total variational distance between distributions $p_1$ and $p_2$. Assume\(^7\) for any policy $\pi, \pi'$ parameterized by $x, y$ it satisfies

\[
\frac{1}{T} \sum_{t=0}^{T-1} \|d_{\pi t} - d_{\pi' t}\|_1 \leq \frac{\delta}{2q^2} \|x - y\| \quad \text{and assume } \|\nabla_x E_{x}[A_{\pi t}](\cdot)\|_* \leq G_2. \text{Then } \nabla_2 F \text{ is uniformly } (1 - q^2)^{-1}\beta\text{-Lipschitz continuous in the second argument.}
\]

By Lemma 3, if $\theta > 1$, then choosing a fixed $q > (1 - \frac{1}{\theta})^{1/T}$ ensures the stability constant of $\tilde{F}$ to be $\tilde{\theta} < 1$. However, stabilizing the problem in this way incurs a constant cost as shown in Corollary 2.

Corollary 2. Suppose $E_{x}[A_{\pi t}][\cdot] < M$ for all $\pi$. Define $\Delta_N = \frac{(\delta \|\pi\|_2^2)^2}{2a} N^2(\theta - 1)$. Then under the assumptions in Lemma 3 and Assumption 3.1, running AGGREVATE with $\tilde{F}$ in (13) and a mixing rate $q$ gives

\[
F(x_N, x_N) \leq \Delta_N + \epsilon_{\Pi, \pi^*} + 2M \min(1, Tq)
\]

6.2 Weighted Regularization

Here we consider another scheme for stabilizing the problem. Suppose $F$ satisfies Assumption 3 and 5. For some $\lambda > 0$, define

\[
\tilde{F}(x, y) = F(x, y) + \lambda R(x)
\]

in which\(^8\) $R(x)$ is an $\alpha$-strongly convex regularization term such that $R(x) \geq 0, \forall x \in \mathcal{X}$ and $\min_{y \in \mathcal{X}} F(x, y) + \lambda R(y) = (1 + \lambda) O(\epsilon_{\Pi, \pi^*})$. For example, $R$ can be $F(\pi^*, \cdot)$ when $\pi^*$ is (close to) optimal (e.g. in the case of DAGGER), or $R(x) = E_{x_{t+1} \sim d_{\pi_{t+1}} E_{x_{t+1} \sim \pi_{t+1}} [d(a, a^*)], \pi}$, where $\pi$ is a policy parameterized and $d(\cdot, \cdot)$ is some metric of space $\mathcal{X}$ (i.e. it uses the distance between $\pi$ and $\pi^*$ as regularization).

It can be seen that $\tilde{F}$ is uniformly $(1 + \lambda)\alpha$-strongly convex in the second argument and $\nabla_2 \tilde{F}$ is uniformly $\beta$-continuous in the second argument. That is, if we choose $\lambda > \theta - 1$, then the stability constant $\tilde{\theta}$ of $\tilde{F}$ satisfies $\tilde{\theta} < 1$.

Corollary 3. Define $\Delta_N = \frac{(\delta \|\pi\|_2^2)^2}{2a} N^2(\theta - 1)$. Running AGGREVATE with $\tilde{F}$ in (14) as the per-round cost has performance satisfies: for all $N > 0$,

\[
F(x_N, x_N) \leq (1 + \lambda) \left( O(\epsilon_{\Pi, \pi^*}) + \Delta_N \right)
\]

Proof. Because $F(x_N, x_N) = \tilde{F}(x_N, x_N) - \lambda R(x_N)$, the inequality can be proved by applying Theorem 2 to $\tilde{F}(x_N, x_N)$.

By Corollary 3, using AGGREVATE to solve a weighted regularized problem in (14) would generate a convergent sequence for $\lambda$ large enough. Unlike using a mixing policy, here the performance guarantee on the last policy is only worsened by a multiplicative constant on $\epsilon_{\Pi, \pi^*}$, which can be made small by choosing a larger policy class.

The result in Corollary 3 can be strengthened particularly when $R(x) = E_{x_{t+1} \sim d_{\pi_{t+1}} E_{x_{t+1} \sim \pi_{t+1}} [d(a, a^*)]$ is used. In this case, it can be shown that $CR(x) \geq F(x, x)$ for some $C > 0$ (usually $C > 1$) (Pan et al., 2017). That is, $F(x, x) + \lambda R(x) \geq (1 + \lambda/C)F(x, x)$. Thus, the multiplicative constant in Corollary 3 can be reduced from $1 + \lambda$ to $1 + \lambda/C$. It implies that simply by adding a portion of demonstrations gathered under the expert’s distribution so that the learner can anchor itself to the expert while minimizing $F(x, x)$, one does not have to find the best policy in the sequence $\{\pi_n\}_{n=1}^N$ as in (8), but just return the last policy $\pi_N$.

7 CONCLUSION

We contribute a new analysis of value aggregation, unveiling several interesting theoretical insights. Under a weaker assumption than the classical result, we prove that the convergence of the last policy depends solely on a problem’s structural property and we provide a tight non-asymptotic bound on its performance in both deterministic and stochastic problems. In addition, using the new theoretical results, we show that the stability of the last policy can be reinforced by additional regularization with minor performance loss. This suggests that under proper conditions a practitioner can just run AGGREVATE and then take the last policy, without performing an additional statistical test to find the best policy, as required by the classical analysis. Finally, as our results concerning the last policy are based on the perturbation of gradients, we believe this provides a potential explanation as to why AGGREVATE has demonstrated empirical success in non-convex problems with neural-network policies.
