Abstract

This paper addresses the issue of measurement errors in visual servoing. The particular contribution is the analysis of the propagation of image error through pose estimation and visual servoing control law. We have chosen to investigate the properties of the vision system and their effect on the performance of the control system. Two approaches are evaluated: i) position-based, and ii) 2 1/2 D visual servoing. The evaluation offers a tool to build and analyze hybrid control systems such as switching or partitioning control.

Key words: visual servoing, measurement errors, error estimation

1 Introduction

The performance of visual servoing methods in the presence of errors has received a considerable amount of attention recently. Particularly, the effect of camera calibration errors has been studied, e.g., [1]. Also, the convergence properties of the control part of the systems are known for most cases, e.g. [2,3]. While the convergence of the system is an essential property, it does not reveal much about the generated trajectory and its uncertainty.

The procedures of camera calibration have improved enormously over the last decade. However, even perfect calibration does not overcome the restriction of the image resolution. The imaging process causes an uncertainty in the control. This paper proposes the use of error propagation in the analysis and comparison of different types of visual servoing methods, i.e., position-based [4] and hybrid [5].

In Figure 1, a general model of visual servoing is presented. It divides the system into three parts: pose estimation, servoing strategy, and control strategy. This model can be used with most position-based and hybrid approaches. It is based on eye-in-hand configuration, and the objective of servoing is defined as bringing the camera to a desired pose with respect to the target. The pose estimation part may compute the full 3-D pose of the target, or it may use homography- or epipolar-based techniques to infer partial pose. In the case of hybrid approaches, image features are directly used to control some degrees of freedom. The choice of servoing strategy defines the error function of the system and thus has a major effect on the trajectory while the control strategy, such as proportional control, affects convergence properties, especially in the case of a moving target.

Fig. 1. System model

To compare the servoing methods with respect to errors in the image, we need a common reference. We use the control output of a Cartesian controller as the reference, since it seems reasonable to study the sensitivity of the system by propagating the errors in the image measurements to the actual actuator motion. Thus, our approach is to predict the uncertainty of the Cartesian control with respect to the uncertainty in the image measurements. We do not wish to analyze uncertainty in the image measurements in detail, but instead model the image uncertainty with a Gaussian distribution, because a wide variety of methods is applicable for the image plane tracking. The division of the servoing model into subsystems allows us not only to compare the behavior of complete systems but also to compare their components.

We use the error analysis to compare position-based visual servoing and the hybrid approach termed 2.5D visual servoing proposed by Malis et al. [5]. The rest of the paper is organized as follows: We survey related work in Section 2 to motivate the research. In Section 3 we present the pose estimation algorithm and analyze its error propagation. Sections 4 and 5 present the position-based and hybrid servoing and their analyses. Section 6 extends the analysis of pose estimation uncertainty to cover all optimization-based algorithms. The ana-
lytical results are verified by experiments in Section 7, which also discusses the merits of the different approaches. Finally, in Section 8, we present a summary and conclusions. Parts of this work has been presented in [6].

2 Related work

The work in this paper is closely related to the analysis of pose estimation algorithms. Pose estimation using a 2-D projection and a 3-D model is a widely studied problem in computer vision, and several approaches exist to solve the problem. Many of the approaches are, however, iterative, which is a disadvantage in the context of visual servoing, where "real-time" is a requirement. There are a few closed form solutions for point feature based pose estimation [7–9]. We have used the algorithm by Fiore [8] together with methods proposed in [10] and [11], but we stress here that any of the algorithms could be used. While for structure-from-motion there are analyses of sensitivity based on linear error propagation (e.g. [11]), according to the authors knowledge no corresponding analyses have been published for the pose estimation. Haralick has demonstrated empirically that pose estimation breaks down when the image noise exceeds a certain threshold [12]. Ansar et al. have presented a sensitivity analysis but their results are upper bounds for the error derived from matrix perturbation theory [9]. Their experiments also reveal that the bounds are highly conservative and thus not well suited for comparing different systems.

The error characteristics of visual servoing are usually investigated from either of the following two points of view: the stability of the closed-loop system, or the steady-state error [13]. It is known that the convergence of position-based visual servoing (PBVS) might be inhibited by the loss of stability in pose estimation [2]. 2.5D servoing does not seem to suffer from this problem [3], unless the partial pose estimation becomes unstable. Deng [13] has proposed use of the steady-state error as a measure of sensitivity of visual servoing. However, if long trajectories are allowed, it is important to know the sensitivity of the system along the trajectory to, for example, predict the set of possible trajectories in the presence of errors. Another approach is to consider the outliers in the image data. Comport et al. [14] have proposed a scheme to increase the robustness by embedding the outlier processing into the control law. Outlier rejection can also be performed in the image processing step [15].

Recently, Gans et al. [16] have proposed switching between position- and image-based servoing. One application of error modeling could be for design of strategies for switching, currently an unsolved problem.
3 Pose estimation

In this section, we first describe the pose estimation algorithm used here. It is based on earlier work by Fiore [8] and Weng et al.[11]. This is followed by the analysis of error propagation.

3.1 Estimation algorithm

The pose estimation, also known as the exterior orientation problem, seeks the similarity transform consisting of translation $t$ and rotation $R$ that brings a set of known 3D feature points $a_i$ into alignment with a set of corresponding image plane projections $(x_i, y_i)$. Without loss of generality, we can assume unit focal length of the camera. Then, translation and rotation are the ones that best satisfy the set of equations

$$l_i [x_i y_i 1]^T = sR(a_i + t), \quad i = 1, \ldots, N$$

where $l_i$ are the projective parameters, $s$ is a scale factor, and $N$ is the number of feature points.

Now, the parameters $l_i$ are first solved following [8]. Let us define the data matrix $P$ for 3D points as

$$P = \begin{pmatrix} a_1 & \cdots & a_N \\ 1 & \cdots & 1 \end{pmatrix}.$$  \hfill (2)

Then, we can find the weight matrix $W \in \mathbb{R}^{N \times (N-4)}$ which satisfies

$$PW = 0$$  \hfill (3)

from the singular value decomposition (SVD) of $P$ as the matrix of the $N-4$ right singular vectors of $P$ corresponding to its null space. Defining the vector of projective parameters $l = [l_1, \ldots, l_N]$, it must satisfy $l = P^T \alpha$ for an unknown vector $\alpha \in \mathbb{R}^4$. Then, $\alpha$ can be found as the solution to the set of homogeneous linear equations

$$C \alpha \equiv \begin{bmatrix} W_{1,1} (\frac{x_1}{y_1}) & \cdots & W_{N,1} (\frac{x_N}{y_N}) \\ \vdots & \vdots & \vdots \\ W_{1,N-4} (\frac{x_1}{y_0}) & \cdots & W_{N,N-4} (\frac{x_N}{y_0}) \end{bmatrix} \mathbf{1} = 0.$$  \hfill (4)

The solution is found as the eigenvector corresponding to the smallest eigenvalue of $C^T C$. This in turn gives the set of projective parameters.

Now, we only need to recover the absolute orientation with scaling. With $l_i$
known, we can write Eq. 1 as

$$\mathbf{b}_i = s \mathbf{R} (\mathbf{a}_i + \mathbf{t}), \quad i = 1, \ldots, N$$

(5)

where \(\mathbf{b}_i = [l, x_i, l, y_i, l]^T\). The unknown scale parameter \(s\) can be solved by centering the two point sets \(\mathbf{a}_i\) and \(\mathbf{b}_i\), and inspecting the ratio between the lengths of the centered vectors. Let \(\mathbf{a}_0\) and \(\mathbf{b}_0\) denote the means of sets \(\mathbf{a}_i\) and \(\mathbf{b}_i\). Then, the centered vectors can be defined as \(\tilde{\mathbf{a}}_i = \mathbf{a}_i - \mathbf{a}_0\) and \(\tilde{\mathbf{b}}_i = \mathbf{b}_i - \mathbf{b}_0\). Now, the optimal least-squares scale can be found from

$$s = \frac{\sum_i \|\tilde{\mathbf{a}}_i\| \|\tilde{\mathbf{b}}_i\|}{\sum_i \|\tilde{\mathbf{a}}_i\|^2}. \quad (6)$$

Next, we want to find the rotation matrix that minimizes the sum of the square errors between the centered point sets, that is, \(\sum_i \|\tilde{\mathbf{b}}_i - s \mathbf{R} \tilde{\mathbf{a}}_i\|^2\), which can also be written in matrix form as \(\|\mathbf{B} - \mathbf{R} \mathbf{A}\|_F^2\), where \(\| \cdot \|_F\) denotes the Frobenius norm. This, so called Orthogonal Procrustes problem, can be solved using SVD as suggested by Fiore, but we choose to solve the rotation using unit quaternions as presented in [11], as they have already proposed a suitable error analysis. The method was actually proposed already in [10].

The unit quaternion \(\mathbf{q}\) representing the rotation can be found as the eigenvector corresponding to the smallest eigenvalue of matrix \(\mathbf{E}\), where \(\mathbf{E}\) is defined as

$$\mathbf{E} = \sum_{i=1}^{N} \mathbf{E}_i^T \mathbf{E}_i = \begin{pmatrix} 0 & (\mathbf{A}_i - \mathbf{B}_i)^T \\ \mathbf{B}_i - \mathbf{A}_i & [\mathbf{A}_i + \mathbf{B}_i]_\times \end{pmatrix}.$$  

(7)

Here \(\mathbf{A}_i\) and \(\mathbf{B}_i\) denote the \(i\)th column of \(\mathbf{A}\) and \(\mathbf{B}\), respectively, and \([\cdot]_\times\) denotes the skew-symmetric matrix corresponding to cross product. When the quaternion \(\mathbf{q} = (q_0, q_1, q_2, q_3)^T\) is known, the rotation matrix can be calculated as

$$\mathbf{R} = \begin{pmatrix} q_0^2 + q_1^2 - q_2^2 - q_3^2 & 2(q_1 q_2 + q_0 q_3) & 2(q_1 q_3 - q_0 q_2) \\ 2(q_1 q_2 - q_0 q_3) & q_0^2 - q_1^2 + q_2^2 - q_3^2 & 2(q_2 q_3 + q_0 q_1) \\ 2(q_1 q_3 + q_0 q_2) & 2(q_2 q_3 - q_0 q_1) & q_0^2 - q_1^2 - q_2^2 + q_3^2 \end{pmatrix}$$  

(8)

Finally, the translation is found from \(\mathbf{t} = s^{-1} \mathbf{R}^T \mathbf{b}_0 - \mathbf{a}_0\) where \(\mathbf{a}_0\) and \(\mathbf{b}_0\) are the point set centroids.

### 3.2 Error analysis

The error analysis in this paper is based on first-order error propagation [17]. The goal of this analysis is to determine the covariance of the pose estimate with respect to the variances of image plane coordinates. While errors also can be analyzed by finding worst case error bounds, these can result in overly
conservative bounds that are suitable only for small errors. In practice, the possible redundancy of data in pose estimation (i.e., having more features than necessary) allows finding stable solutions also in the presence of noise. In this paper, it is assumed that the errors in the pose estimate result from the noise in the image coordinates of features. Their sources include spatial quantization, feature detection, and camera distortion. However, we assume that there is no systematic calibration error and thus the image noise can be modeled as zero-mean random variables. It is further assumed that the errors between points are uncorrelated.

Let $\mathbf{x}$ be the vector of image coordinates of features such that

$$\mathbf{x} = (x_1, \ldots, x_N, y_1, \ldots, y_N)^T.$$ 

We can formulate the error analysis problem as finding the matrices $\mathbf{D}_t$ and $\mathbf{D}_R$ such that $\delta_t = \mathbf{D}_t \delta_x$ and $\delta_R = \mathbf{D}_R \delta_x$ are linear error estimates in $t$ and $R$ with respect to errors in $\mathbf{x}$. It is evident that $\mathbf{D}_t$ and $\mathbf{D}_R$ depend on the values of both $\mathbf{x}$ and $\mathbf{a}_i$s, that is, image measurements and the object model. Note that matrix $\mathbf{R}$ must be represented as a vector $\mathbf{r}$ by concatenating the columns of the matrix into a single vector. Thus, $\delta_R$ is the error in this vector. For vectors, let $\Gamma$ denote the covariance matrix, e.g., $\Gamma_x = E[\delta_x \delta_x^T]$.

The error is now propagated through the pose estimation algorithm. First, it can be seen that $\mathbf{W}$ in (3) depends only on matrix $\mathbf{P}$ where there is no associated uncertainty. Now, the uncertainty in matrix $\mathbf{C}$ (4) can be found by finding the matrix $\mathbf{G}_C$ that represents the transform from $\mathbf{x}$ to $\mathbf{c}$ (and $\delta_c = \mathbf{G}_C \delta_x$), the vector representation of matrix $\mathbf{C}$. This operation is linear so no approximations are needed. The matrix is easily found to be

$$\mathbf{G}_C = \left( \begin{array}{cccccc} Q_1 & 0 & Q_2 & 0 & Q_3 & 0 \\ 0 & Q_1 & 0 & Q_2 & 0 & Q_3 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & Q_4 \end{array} \right)^T$$

where

$$Q_i = \left( \begin{array}{cccc} W_{1,1}p_{1,1} & \cdots & W_{1,N-1}p_{1,1} \\ \vdots & \vdots & \vdots \\ W_{N,1}p_{N,1} & \cdots & W_{N,N-1}p_{N,1} \end{array} \right).$$

Next, the linear estimate for the error in $\mathbf{C}^T \mathbf{C}$ is found. Denoting the error matrix corresponding to vector $\delta_c$ by $\Delta_C$, the linear estimate is

$$\Delta_{C^T \mathbf{C}} \approx \mathbf{C}^T \Delta_C + \Delta_C^T \mathbf{C}.$$ 

Using the vector notation, this can be written as

$$\delta_{C^T \mathbf{C}} \approx \mathbf{G}_{C^T \mathbf{C}} \delta_c = \mathbf{G}_{C^T \mathbf{C}} \mathbf{G}_C \delta_x = \mathbf{D}_{C^T \mathbf{C}} \delta_x$$

where $\mathbf{G}_{C^T \mathbf{C}}$ is determined using Eq. 10.
To propagate the error through the eigenvalue decomposition, we use the result presented by Weng et al. in [11]. The linear error term in $\alpha$, the smallest eigenvector of $C^T C$, is given by

$$
\delta_\alpha \approx H \Delta H^T \Delta_{C^T C} \alpha \\
= H \Delta H^T [\alpha_1 I_4 \quad \alpha_2 I_4 \quad \alpha_3 I_4 \quad \alpha_4 I_4] \delta_{C^T C} \\
= G_\alpha \delta_{C^T C} = G_\alpha D_{C^T C} \delta_x = D_\alpha \delta_x \tag{12}
$$

where $H$ is the matrix of eigenvectors of $C^T C$ and $\Delta$ is given in terms of the eigenvalues $\lambda_i$ as

$$
\Delta = \text{diag} \left\{ 0, (\lambda_1 - \lambda_2)^{-1}, (\lambda_1 - \lambda_3)^{-1}, (\lambda_1 - \lambda_4)^{-1} \right\}.
$$

As the projective parameters depend linearly on $\alpha$, we can find the associated error as $\delta_1 = P^T \delta_\alpha \approx P^T D_\alpha \delta_x = D_\delta \delta_x$.

Now we continue to propagate the errors to $b_i$. Let

$$
\delta_B = [\delta_{I_1 x_1}, \cdots, \delta_{I_N x_N}, \delta_{I_1 y_1}, \cdots, \delta_{I_N y_N}, \delta_{I_1}, \cdots, \delta_{I_N}]^T.
$$

The linear approximation for the error is

$$
\delta_B \approx \begin{pmatrix} \text{diag}(I) & 0 & \text{diag}(x_{1\cdots N}) \\ 0 & \text{diag}(I) & \text{diag}(y_{1\cdots N}) \end{pmatrix} \begin{pmatrix} \delta_x \\ \delta_1 \\ \delta_1 \end{pmatrix} = \begin{pmatrix} \text{diag}(I) + \text{diag}(x_{1\cdots N}) D_1 & 0 \\ 0 & \text{diag}(I) + \text{diag}(y_{1\cdots N}) D_1 \end{pmatrix} \delta_x = D_B \delta_x \tag{13}
$$

In the following, we will skip the details on linear steps of the error propagation to keep the discussion as brief as possible while still stating each approximation during the nonlinear steps. Centering the set of vectors $b_i$ does not involve nonlinear operations so no approximations need to be done to find the error in $\tilde{b}_i$. Then, $\delta_B \approx D_B \delta_x$. In calculating the scale, $\delta_s \approx G_s \delta_B$ where

$$
G_s = \frac{1}{\sum_i \|\tilde{a}_i\|^2} \left( \frac{b_{i_1} \|a_1\|}{\|b_i\|} \cdots \frac{b_{i_N} \|a_N\|}{\|b_N\|} \right) \tag{14}
$$

As stated before, the rotation matrix is now estimated using unit quaternions. This encompasses another case of determining the eigenvector corresponding to the smallest eigenvalue of a matrix $E$, which is a non-linear combination of previously known variables. Its error $\delta_E$ can be found by first finding the errors in $E_i$ which are linear with respect to errors in $B$. The error in the matrix multiplication $E_i^T E_i$ can be propagated as in (10). Finally, the error in $E$ can be approximated as a matrix product $\delta_E = G_E [\delta_B^T, \delta_s]^T$. 

The error can now be propagated in a similar fashion as shown above for vector $\alpha$ in (12). As a result, we get the unit quaternion $q$ that represents the rotation and its error with respect to the errors in input $G_q \delta E = D_q \delta x$. We can estimate the first order perturbation of $R$ as $\delta_R \approx G_R \delta_q = D_R \delta x$ where

$$G_R = 2 \begin{pmatrix} q_0 & q_3 & -q_2 & -q_3 & q_0 & q_1 & q_3 & -q_1 & q_0 \\ q_1 & q_2 & q_3 & q_2 & -q_1 & q_0 & q_3 & -q_0 & -q_1 \\ -q_2 & q_1 & -q_0 & q_1 & q_2 & q_3 & q_0 & q_3 & -q_2 \\ -q_3 & q_0 & q_1 & -q_0 & -q_3 & q_2 & q_1 & q_2 & q_3 \end{pmatrix}^T.$$ (15)

The error in the translation can finally be estimated from the first-order Taylor expansion as

$$\delta_t \approx \frac{1}{s}(R^T \delta b_0 + \Delta R^T b_0) - \frac{1}{s^2} \delta s R^T b_0 = G_t \delta E = D_t \delta x$$ (16)

In summary, we have expressed the perturbations in the pose estimate as a linear transformation of the perturbations in the input image. This allows us also to write the covariance matrices of the pose parameters as

$$\Gamma_R = D_R \Gamma_x D_R^T \quad \Gamma_t = D_t \Gamma_x D_t^T.$$ (17)

The following two sections outline two visual servoing methods and relate the uncertainty in the pose estimate presented in this section to the uncertainty in the control.

### 4 Position Based Visual Servoing

In position-based visual servoing (PBVS), the task function is defined in terms of the pose transformation between the current and the desired position, which can be expressed as the transformation $^{c}T_o$. The input image is usually used to estimate the camera to object transformation $^{c}T_o$ which can be composed with the object to desired pose transformation $^{o}T_e$ to find the relation from the current to the desired pose. By decomposing the transformation matrices into translation and rotation, this can be expressed as

$$^{c}T_e = ^{c}T_o \cdot ^{o}T_e = \begin{pmatrix} ^{c}R_o & ^{c}t_o \\ 0 & 1 \end{pmatrix} \begin{pmatrix} ^{o}R_e & ^{o}t_e \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} ^{c}R_e & ^{c}t_o \cdot ^{o}t_e \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} ^{c}R_e & ^{c}t_e \cdot ^{o}t_o \end{pmatrix}.$$ (18)

The task function for position is then the vector $^{c}t_e$. For orientation, the rotation matrix can be decomposed into axis of rotation $u = (u_1, u_2, u_3)^T$ and
angle $\theta$, which can be multiplied to attain the task function $u\theta$ using

$$
\theta = \arccos \left( \frac{\text{trace}(R) - 1}{2} \right)
$$

$$
\sin \theta = \sqrt{1 - \left( \frac{\text{trace}(R) - 1}{2} \right)^2}
$$

$$
u_1 = \frac{R_{32} - R_{23}}{2 \sin \theta} \quad u_2 = \frac{R_{13} - R_{31}}{2 \sin \theta} \quad u_3 = \frac{R_{21} - R_{12}}{2 \sin \theta}.
$$

(19)

Starting from the result of the analysis of pose estimation, we first inspect the camera to object transformation. The rotation matrix $R$ in the image formation model in Eq. 1 is the desired rotation from the camera to object frames $^cR_o$. The reference frame for the translation is expressed with respect to the object rather than the camera. Thus, we need to rotate the translation vector to correspond to camera frame axes, and find the uncertainty for this rotated vector using the uncertainties in both the rotation matrix and the translation vector. The uncertainty can thus be expressed as

$$
\delta_{t_o} \approx G_{t_o}(\delta_{t_o}) = D_{t_o}^T \delta_x = D_{t_o} \delta_x.
$$

Assuming that there is no uncertainty associated with the desired position, the error in the rotation from the current to desired pose can be approximated as $\Delta_{R_c} \approx \Delta_{R_o}^c \delta_{R_c}$. For the translation, the corresponding errors can be written as $\delta_{t_c} \approx \Delta_{t_c}^c \delta_{t_c} + \delta_{t_o} = G_{t_o}(\delta_{t_o}) + \delta_{t_o} = D_{t_o} \delta_x$. Now, what remains is to transform the rotation matrix into a control vector for rotation. We use the $u\theta$ form and estimate the errors as $\delta_{u\theta} \approx G_{u\theta} \delta_{u\theta} = D_{u\theta} \delta_x$, where $G_{u\theta} = \mathbf{1} + \theta \delta_u + \theta^2 G_u \delta_{u\theta} + \theta^3 G_u(\delta_{u\theta}, \delta_{u\theta})$. From (19) we get

$$
\tan \theta = \frac{2 \sin \theta}{\text{trace}(R) - 1}.
$$

(20)

Now, we can write

$$
G_{\theta} = -\frac{1}{2 \sin \theta} (1, 0, 0, 0, 1, 0, 0, 0, 0, 1)
$$

(21)

and

$$
G_u = \begin{pmatrix}
0 & 0 & 0 & 0 & \frac{1}{2 \sin \theta} & 0 & \frac{1}{2 \sin \theta} & 0 & -\frac{1}{2 \sin \theta} & \frac{1}{2 \sin \theta} \\
0 & 0 & \frac{1}{2 \sin \theta} & 0 & 0 & 0 & \frac{1}{2 \sin \theta} & 0 & 0 & -\frac{1}{2 \sin \theta} \\
0 & \frac{1}{2 \sin \theta} & 0 & -\frac{1}{2 \sin \theta} & 0 & 0 & 0 & 0 & 0 & \frac{1}{2 \sin \theta}
\end{pmatrix}.
$$

(22)

Assuming that a proportional control is used, the error in the control vector $v$ is finally estimated as

$$
\delta_v = -\lambda \begin{pmatrix}
\delta_{t_o} \\
\delta_{u\theta}
\end{pmatrix}
\approx \begin{pmatrix}
-\lambda D_{t_o} \\
-\lambda D_{u\theta}
\end{pmatrix} \delta_x = D_v \delta_x.
$$

(23)
This allows us also to approximate the covariance matrix of the control error from $\Gamma_\nu = E[\delta_\nu \delta_\nu^T] \approx D_\nu \delta_\nu D_\nu^T$.

5 Hybrid Visual Servoing

The hybrid visual servoing approach, called 2.5D servoing, was originally presented as a method suitable for avoiding the target leaving the field of view of the camera (a PBVS problem), and to perform servoing without a complete 3D model of the target [5]. It is based on partial pose estimation using a scaled Euclidean reconstruction with a homography decomposition. However, it can be also used with full pose estimation.

We now briefly present the 2.5D servoing with full pose estimation used in our work. The control scheme is based on controlling the orientation using the estimated 3-D rotation between the current and desired poses and driving the vector $u\theta$ to zero just as in PBVS. The position in turn is controlled using a single point feature that is driven towards its desired location in both image coordinates and depth. Thus, the visibility of the feature during the servoing sequence is guaranteed. The task vector can be defined as

$$e = [x - x^*, y - y^*, \log(Z/Z^*), \theta u^T]^T$$  \hspace{1cm} (24)

where $(x, y)$ is the position of the control point in the image, $Z$ is its depth, and asterisks denote the desired values. The motion control law is then

$$v = -\lambda \begin{pmatrix} L^{-1}_o & -L^{-1}_o L_{u\omega} \\ 0 & 1 \end{pmatrix} e$$  \hspace{1cm} (25)

where

$$L^{-1}_o = \begin{pmatrix} -Z & 0 & -xZ \\ 0 & -Z & -yZ \\ 0 & 0 & -Z \end{pmatrix}$$  \hspace{1cm} (26)

and

$$L_{u\omega} = \begin{pmatrix} xy & -(1+x^2) & y \\ 1+y^2 & -xy & -x \\ -y & x & 0 \end{pmatrix}.$$  \hspace{1cm} (27)

In our framework (Fig. 1), the rotation $u\theta$ and the depth $Z$ are calculated using the pose estimation while $x$ and $y$ result directly from image measurements. $Z$ can thus be written as

$$[X, Y, Z]^T = cT_o [a^T, 1]^T.$$  \hspace{1cm} (28)

The sensitivity for the rotation is identical to that presented in the previous section. However, we desire to estimate the error in the control vector to recognize correlations between the errors in different variables. The error in
the depth can be approximated in terms of the errors on estimated rotation and translation as

\[ Z = G_Z[D_R^T, D_t^T]^T \delta_x \]

where \( G_Z \) can be determined from (28). Now, the uncertainty in the control output \( v \) can be approximated as

\[ v = G_v[\delta_x, \delta_y, \delta_Z, \delta_u, \delta_t]^T = D_v \delta_x \]

where \( G_v \) can be determined from

\[
G_v = \begin{pmatrix}
G_{v1} & G_{v2}
\end{pmatrix}
\]

\[
G_{v1} = \begin{pmatrix}
-Z - Z \log \frac{Z}{R} & Zu3\theta & -2x + x^* - x \log \frac{Z}{R} - u2\theta + yu3\theta \\
-Z u3\theta & -Z - Z \log \frac{Z}{R} & -2y + y^* - y \log \frac{Z}{R} + u1\theta - xu3\theta \\
Z u2\theta & -Z u1\theta & -\log \frac{Z}{R} - 1 - yu1\theta + xu2\theta \\
0 & 0 & 0 \\
0 & 0 & 0 \\
0 & 0 & 0
\end{pmatrix}
\]

\[
G_{v2} = \begin{pmatrix}
0 & -Z \theta & -Z u3 + yZ u3 \\
-Z \theta & 0 & zZ u3 - xZ u3 \\
-y \theta & xZ \theta & 0 \\
0 & 0 & 0 \\
0 & 0 & 0 \\
0 & 0 & 0
\end{pmatrix}.
\]

Then, the covariance of the control is approximately \( \Gamma_v \approx D_v \delta_x D_v^T \).

6 Optimization based pose estimation

In this section, we show how to extend the results of the error estimation of pose estimation to cover all optimization based pose estimation algorithms. The analysis method does not need to take into account a particular optimization method, because it only estimates how the location of the minimum changes when the input of minimization is disturbed. The analysis is based on [17].

Optimization-based pose estimation can be defined as minimizing the image plane error

\[ e = \sum_i \left[ \left( x_i - \frac{[1, 0, 0]^T R(a_i + t)}{[0, 0, 1]^T R(a_i + t)} \right)^2 + \left( y_i - \frac{[0, 1, 0]^T R(a_i + t)}{[0, 0, 1]^T R(a_i + t)} \right)^2 \right]. \]

While the rotation matrix \( R \) has nine entries, it has only three degrees of freedom. In minimization, the rotation can be represented as a three-element vector \( w = \theta u \), which encodes the rotation as an angle-axis-pair.

Now, first-order error propagation can be used to inspect the effect of uncertainty in 2-D and 3-D point coordinates to the location of the minimum. Let \( \Theta = \{ t, w \} \) denote the true pose parameters and \( X = (a_1, x_1, y_1, \ldots, a_N, x_N, y_N)^T \) denote the set of coordinates without errors. The gradient of the error function
with respect to the pose parameters can now be written as

$$g(X, \Theta) = \frac{\partial e(X, \Theta)}{\partial \Theta}. \tag{32}$$

By denoting the measurements by $\hat{X} = X + \Delta X$ and corresponding pose parameters by $\hat{\Theta} = \Theta + \Delta \Theta$, we can write the first order Taylor approximation for the gradient at $(X, \Theta)$ using the measurements as

$$g(X, \Theta) = g(\hat{X}, \hat{\Theta}) - \frac{\partial g^T(\hat{X}, \hat{\Theta})}{\partial X} \Delta X - \frac{\partial g^T(\hat{X}, \hat{\Theta})}{\partial \Theta} \Delta \Theta. \tag{33}$$

Now, the gradient of the error $g(\cdot)$ must be zero at both $(X, \Theta)$ and $(\hat{X}, \hat{\Theta})$, so to a first order approximation

$$\Delta \Theta = -\left(\frac{\partial g^T(\hat{X}, \hat{\Theta})}{\partial \Theta}\right)^{-1} \frac{\partial g^T(\hat{X}, \hat{\Theta})}{\partial X} \Delta X = D_{\Delta \Theta} \Delta X. \tag{34}$$

The difference of this to the analysis of Sec. 3.2 is that now in addition to the measurement uncertainty, also the uncertainty of the 3D model can be taken into account. The uncertainty in pose parameters can then be propagated through visual servoing laws as shown in Sections 3 and 4. The analytical forms of the gradients can be calculated using (31) and (32) but they are omitted here for the sake of brevity.

Like with closed-form pose estimation, we can estimate the covariance of $\Theta$ by denoting the covariance matrix of $X$ by $\Gamma_X$ as

$$\Gamma_{\Theta} = D_{\Delta \Theta} \Gamma_X D_{\Delta \Theta}^T \tag{35}$$

7 Experimental evaluation

In this section, we present the experiments performed to validate the presented error analysis and to compare position based and hybrid visual servoing. We begin by considering the pose estimation algorithm, then consider the visual servoing approaches separately, and conclude by discussing the relative properties of the approaches. We have also performed experiments on the estimation of uncertainty of optimization-based pose estimation, which indicate that the estimates are valid. These experiments are not presented in this paper for the sake of brevity.
7.1 Pose estimation

The validity of the analysis was evaluated using Monte-Carlo simulation. Figure 2 shows the validity region of the error estimation. The deviation of the translation with respect to image error is presented on the left in Fig. 2, while the deviation in the rotation angle is on the right. The image coordinates used are the normalized camera coordinates, i.e., after internal camera calibration. The lines present the predicted deviations while the crosses are the measured estimates from 1000 Monte-Carlo simulations. The breakdown point of the error estimation is when the deviation in the image coordinates is approximately $\sigma \approx 10^{-2.5}$. Naturally, the breakdown point depends on the feature point configuration. The 6-feature target and its point deviations used in the experiment is shown on the left in Fig. 3. Four of the feature points lie in a plane while two are displaced by a small amount. It should be noted that the breakdown point of the error estimation coincides with the breakdown point of the pose estimation, that is, the error estimation becomes invalid when the pose estimation algorithm starts to break down. An obvious restriction of the linear error estimation is its inability to predict the breakdown point as it is primarily a higher order phenomenon.

![Fig. 3. (left) Deviation of image points for $\sigma = 10^{-2.5}$; (right) Image plane trajectories for PBVS.](image)

The point configuration has a remarkable effect on the pose estimation accuracy. To investigate this, an experiment with random configurations was performed. Each configuration had 8 points uniformly distributed inside a unit cube. Again, we used Monte-Carlo simulations to examine the uncertainty. In Fig. 4, the measured and predicted uncertainties are shown for 50 random configurations for two translational axes of freedom. The solid lines are the predictions and the crosses the Monte-Carlo estimates. The predictions show high correlation to the Monte-Carlo measurements, with correlation coeffi-
Fig. 4. Effect of point configuration on two axes.

Fig. 5. Effect of distance on (left) translation; (right) rotation angle.

Another parameter affecting the accuracy is the distance to the target. A set of Monte-Carlo experiments was performed assuming constant deviation in image coordinates. Figure 5 shows how the uncertainty grows as the distance increases. The solid lines are again the predictions and the crosses are Monte-Carlo estimates. The errors are scaled with an exponential factor to demonstrate the error behavior. The graph on top shows the cubic root of the translational error on one axis with respect to the distance while the bottom one is the square root of the error in the rotation angle. It is easy to see that the translation error is proportional to the third power of the distance while the rotational error is proportional to the squared distance. The cubic nature of the translational error was observed for all three axes.

The analysis predicted also very high correlation between the translation in x-axis and rotation around y-axis, as well as vice versa. This translation-rotation-ambiguity is a well-known phenomenon in structure-from-motion.

### 7.2 Position-based servoing

The following experiments assume a servoing task where the camera is initially rotated around all axes and positioned relatively far away from the goal position (around ten times the desired distance). This allows us to evaluate the
effect of the distance to the servoing and also investigate the rotation around different axes. The target is the same as presented in the previous section. The trajectories of the features in the image plane are shown on the right in Fig. 3.

The validity of the analysis was verified by displacing the feature locations using a known error distribution and measuring the deviation of the control output. In Fig. 6, the predicted and measured deviations in the translational velocities in $y$ (dotted line) and $z$ (dashed line) are shown, as well as in the rotational velocities around the same axes. The figure shows that the measured and predicted deviations correspond very well, which indicates that the theoretic analysis is valid.

Figures 7 and 8 demonstrate the error behavior of position-based servoing. The results are presented in both world and camera frames because the world frame is the most natural way to inspect the error in terms of the Cartesian controller, while the camera frame reveals information about the directional nature of the error. In the figures, the solid line corresponds to $x$-axis translation and rotation, the dotted line to $y$-axis, and the dashed line to $z$-axis.

Left column in Fig. 7 shows the negative exponential velocity of the Cartesian control in PBVS. The absolute deviations in the control are presented in the middle of Fig. 7, and relative (deviation divided by the control output) on right. Fig. 8 presents the behavior in camera frame. It can be seen that the control in the direction of the camera optical axis is much more reliable in terms of image errors, as is also the rotation around the optical axis (coinciding with the world $y$-axis in the goal position). There seems to be little difference in the control in the axes perpendicular to the optical axis near the goal position, but initially when the object is not yet aligned to the image plane, there is some difference in the accuracy. The maximum shown in top right subfigure of Fig. 8 is caused by the zero-crossing of the corresponding control (note that this zero-crossing occurs only in the camera frame, not in the world frame where PBVS guarantees a trajectory along a straight line). Another observation to make is that the relative error has a minimum along the trajectory, when the distance to the target is already quite small, but the target is still not precisely aligned. After this minimum, the relative error continues to increase to a level.
that would make the servoing impossible if the error would exist in practice.

The relative errors can be used to assess the validity of the servoing in the direction of a certain axis so that when the relative error becomes dominant (say, more than third of the control), the control in that axis can begin to diverge. The target is almost perfectly aligned in \( z \)-coordinate of the world frame, so the relative error in \( z \)-translation is very high throughout the motion, which seems to suggest that there is no reason to control that axis.
7.3 Hybrid visual servoing

The same control task used with PBVS was also used with the hybrid approach. The results of the analysis were verified by an experiment, which is presented in Fig. 9. The predicted deviations seem to follow the measurements well, which suggests that the analysis is valid.

![Fig. 9. Measured and predicted deviations in HYBVS control output: (left) translation; (right) rotation.](image)

The error behavior of HYBVS can be seen in Fig. 10 for the world frame and in Fig. 11 for the camera frame. In some respects, the behavior is similar to PBVS. Most importantly, the errors in the translation along the optical axis and in the rotation around it are considerably smaller than for the axes parallel to the image plane. The behavior in rotation resembles that of PBVS, but it is important to note that they are not identical, as the systems have a different trajectory. It is easy to notice that HYBVS has a faster convergence in the depth (Figs. 7 and 10), and this seems to be the reason for it to attain the constant error region of z-axis rotation sooner (Figs. 7 and 10). The relative errors show another characteristic of HYBVS, the occurrence of zero-crossings in the Cartesian control. This can be seen easily from the strong peak of the relative error in translation (Fig. 7). The relative errors also suggest the regions where the control is likely to diverge due to the errors in pose estimation. For HYBVS it seems that translation can be controlled at least to some degree in x and y and rotation in y and z. Now, the translation-rotation ambiguity can be again seen as the z-axis translation corresponds to x-axis rotation in the world frame.

7.4 Discussion

A common reference trajectory needs to be defined in order to compare PBVS and HYBVS uncertainties with respect to time. Fig. 12 presents the estimated errors of HYBVS control when the camera is moved along the trajectory generated using PBVS. Thus, the camera location with respect to time corresponds to Figs. 7 and 8. The errors are presented in the world frame. The absolute and relative errors for translation in Fig. 12 correspond to Fig. 7. For the ro-
Fig. 10. HYBVS behavior in world frame: (left column) Velocity; (middle column) Absolute errors; (right column) Relative errors; (top row) translation; (bottom row) rotation.

Fig. 11. HYBVS behavior in camera frame: (left column) Velocity; (middle column) Absolute errors; (right column) Relative errors; (top row) translation; (bottom row) rotation.

tation part, the errors are not shown, as they would be identical to the PBVS case since the rotation control is identical. PBVS has clearly smaller absolute errors than HYBVS in the beginning. A possible explanation for this is that the methods follow a different trajectory. Another issue is the ability of PBVS to use all feature points for the pose estimation, while HYBVS uses only a single point to control the trajectory parallel to the image plane. The relative errors have some similarities, in particular the order of the axes is the same. For the translation along $y$ (which is closest to the optical axis, and which has the longest initial distance), the relative error amplitudes seem to be comparable. For the $x$-axis, which has some initial error, PBVS is initially less prone
to errors, while later in the trajectory the errors become comparable. For the z-axis, HYBVS has slightly smaller error, but it is unlikely that either can be used for efficient control, as the error is large. In addition, the reason that HYBVS has smaller relative error is that it initially controls the axis away from the point of convergence as was seen in the existence of the zero-crossing discussed earlier.

8 Summary and Conclusion

In this paper, we have analyzed the effect of measurement errors in visual servoing. The main contribution of this paper is the idea of the propagation of image error through pose estimation and visual servoing control law. In particular, we have investigated the properties of the vision system and their effect to the performance of the control system. Two servoing approaches have been evaluated: i) position-based, and ii) 2 1/2D visual servoing. Our analysis is limited to one particular pose estimation algorithm and two visual servoing approaches, which we feel nevertheless provides novel information and serve as an example that our analysis framework is suitable for visual servoing. It is possible to extend the results to other servoing strategies and pose estimation methods. Particularly, we show how any optimization-based pose estimation approach can be analyzed. However, we feel that a closed-form solution is better suited to visual servoing because of real-time issues involved. We believe that our evaluation offers a valid tool to design hybrid control systems based on, for example, switching [16] or partitioning [5].

Our future work will investigate the following questions: Can we use this measure of uncertainty to control only viable degrees of freedom? For example, to first control the robot to a more reasonable distance from an initially distant pose and then, when close to target, control the more difficult degrees of freedom. Recently, Mansard and Chaumette have proposed a stacked controller architecture which could be used to implement this type of control [18]. We also want to propagate the error through the pure image based visual servoing control law and compare this to the results presented here. The last question we want to answer is: Can we use this type of evaluation to find favorable
feature configurations so to obtain optimal or stable behavior, especially in
the case of image based visual servoing, [19].
